### Abstract

**Background:** A fundamental duty of the immune system is to defend against infectious agents. Significant abnormalities were reported in immune parameters of hypothyroid and hyperthyroid patients. In this study, we aim to assess various quantities of antibodies against the tetanus toxin (anti-TT) in hypothyroid and hyperthyroid patients.

**Materials and Methods:** Anti-TT levels were measured in serum samples from 50 hypothyroid patients, 50 hyperthyroid patients, and 50 euthyroid individuals, using the ELISA method. Besides, the minimum protective quantity of anti-TT was considered 0.1 IU/mL.

**Results:** Seroprotective rates against tetanus were 100, 80, and 96.0 % in euthyroid, hypothyroid, and hyperthyroid groups with the means of  $3.52 \pm 0.31$ ,  $1.62 \pm 0.21$ , and  $4.07 \pm 0.32$  IU/ml, respectively. Accordingly, hypothyroid patients exhibited lower anti-TT levels and seroprotective rates than the euthyroid group ( $P < 0.001$  and  $P < 0.004$ , respectively). Besides, in the hypothyroid group, anti-TT quantities and seroprotective rates were lower than those in hyperthyroid individuals ( $P < 0.001$  and  $P < 0.03$ , respectively).

**Conclusions:** The findings demonstrated lower immunity and higher susceptibility to tetanus in patients with hypothyroidism. However, more studies are needed to be conducted in this field to provide more data to be considered in health programs.

### Introduction

Contamination of wounds with spores of gram-positive anaerobic bacillus *Clostridium (C) tetani* and the release of a bacterium-derived neurotoxin

lead to tetanus [1]. Although an efficient anti-tetanus vaccine is available, tetanus has remained a crucial public health concern. Around one million deaths occur annually due to this disease worldwide [1, 2]. Tetanus is infrequent in healthy

individuals receiving complete vaccine doses; however, insufficient and incomplete immunization against tetanus as well as poor care of the wounds are related to tetanus, especially in ages over 65 [3]. The Advisory Committee on Immunization Practices (ACIP) advised a series of immunizations, including five doses of the Diphtheria-Tetanus-Pertussis (DTP) vaccine for infants and young children with single immunization using TT, the reduced Diphtheria-Pertussis (TdP) vaccine for adolescents and adults, as well as a booster vaccine dose of the Td vaccine every 10 years or when wound management is needed [1, 4, 5]. In Iran, vaccination with a local DTP vaccine (manufactured by the Razi Institute) began in 1950 [6].

Hypothyroidism is frequent in regions with adequate levels of iodine so that the rate of hypothyroidism is about 1-2%, which increases to about 7% in individuals aged 85-89 [7]. Besides, the rate of overt hyperthyroidism is about 0.2-1.3% in regions with adequate iodine. The rate of overt hypothyroidism is about 0.2-5.3% in Europe and 0.3-3.7% in the USA [7]. Annual frequencies of subclinical and overt hypothyroidism were reported to be about 7.62 and 2.0 per thousand, respectively, in Tehran, a region with adequate iodine [8].

A strong bidirectional interplay exists between the immune system and the neuroendocrine system. Thyroid-related hormones can influence the functions of various types of leukocytes, including lymphocytes, natural killer cells, monocytes, and macrophages [9]. Major abnormalities were reported in immune parameters of hypothyroid and hyperthyroid patients [10, 11]. Patients with hyperthyroidism commonly display an imbalance in immune responses, including unusual antibody production [9]. Hypothyroid patients suffer impairments in their immune system and vulnerability to infections [9]. Vaccination provides significant protection against infectious diseases. However, vaccination-mediated immunity has not been evaluated adequately in patients suffering from thyroid disorders. This investigation was conducted to measure the serum quantities of antibodies against the tetanus toxin (anti-TT) in hypothyroid or hyperthyroid patients.

## Materials and Methods

Two groups of patients were enrolled in this descriptive cross-sectional study, who included 50 hypothyroid patients (aged  $38.8 \pm 16.15$ ) and 50 hyperthyroid patients (aged  $37.2 \pm 16.17$ ). They had been referred to the Pathobiological

Laboratory affiliated to the Rafsanjan University of Medical Sciences (Rafsanjan, Iran). Hypothyroid and hyperthyroid disorders were diagnosed according to clinical and paraclinical evidence.

Apart from clinical observations, such as weight loss, tachycardia, arrhythmia, increased appetite, nervousness, anxiety, fatigue, muscle weakness, and skin thinning, some other indices, including decreased serum quantities of TSH, elevated serum amounts of T3, and T4 hormones ( $T4 > 160$  nmol/L,  $T3 > 3.6$  nmol/L,  $TSH < 0.35$  mIU/L) were used in diagnosing hyperthyroidism. Development of symptoms (fatigue, sensitivity to cold, weight gain, constipation, muscle weakness, joint swelling, thinning hair, irregular menstrual periods, depression, and enlarged thyroid), increased serum quantities of TSH accompanied with reduced serum amounts of T3 and T4 ( $T4 < 60$  nmol/L,  $T3 < 1.6$  nmol/L,  $TSH > 3.5$  mIU/L) were regarded as the criteria for hypothyroidism diagnosis [10]. Interpretation of T4 levels with the corresponding TSH was considered a high-accuracy index for the diagnosis of hypothyroidism or hyperthyroidism [12].

The euthyroid group that included gender-matched healthy individuals (aged  $37.4 \pm 14.50$ ) with normal tests for thyroid hormones were enrolled as the control ( $T4$ : 60-160 nmol/L,  $T3$ : 1.8-3.6 nmol/L,  $TSH$ : 0.35-3.5 mIU/L). Taking medications for hypothyroidism or hyperthyroidism, smoking cigarettes, having a surgery history, as well as suffering from illnesses, such as infectious diseases, malignant diseases, allergies, and doubtful immunological disorders were considered as the exclusion criteria. The participants were not treated with immunomodulating drugs and had normal cell blood counts (CBC), lipids profiles, as well as liver and renal-related function tests.

The Ethics Committee of Rafsanjan University of Medical Sciences confirmed the procedure of this research and written informed consent was obtained from all participants. Besides, a peripheral blood specimen (2-4 mL) was obtained from each participant, and their serums were isolated and kept at  $-20^{\circ}\text{C}$ .

As already mentioned, universal immunization with the DTP vaccine started in 1950 in Iran [6]. As the participants were born after that date, they routinely received the DTP vaccine. Besides, primary immunization had been achieved using three injections at the ages of 2, 4, and 6 months, followed by three booster injections at the ages of 18-24 months, 4-6 years, and 18-24 years [6].

Serum quantities of the specific anti-TTA were detected using ELISA commercial kits (IBL-Hamburg GmbH, Hamburg, Germany) as explained previously [13]. In brief, 100  $\mu\text{L}$  of

standard and serum specimens was pipetted into the specified ELISA plate wells covered with a tetanus toxin. Next, the plates were incubated at room temperature (RT) for 60 minutes to bind the specific antibodies in the samples to the coated antigen in the wells. Besides, the wells were washed using a washing buffer (by a 300 µL/well 4 times) to remove the unbounded antibodies. Next, 100 µL conjugate (the enzyme-labeled antibody against human IgG) was added to the wells. After the incubation time for 30 minutes at RT, the wells were washed again as described. Next, 100 µL of a substrate solution (Tetramethylbenzidine) was added to the wells, and the plate was incubated at RT for 20 minutes in the dark. The enzyme activity

was terminated by adding sulfuric acid (50 µL/well). Besides, the optical density of the wells was measured at 450 nm using an ELISA reader system. The density of the developed color was equal to the concentration of the anti-TT. According to the manufacturer's instructions, the anti-TT concentrations expressed as IU/mL and the levels of ≥ 0.1 IU/mL were regarded as protective concentrations of the antibodies. ELISA sensitivity was 0.004 IU/ml. The student's t-test and the Chi-square test were used for the analysis of the results using SPSS software (V21.0, Chicago, IL, USA), and a p-value less than 0.05 was considered significant.

**Fig. 1.** Seroprotective rates against tetanus in healthy subjects and patients with hypothyroidism and hyperthyroidism; the seroprotective rate against tetanus was lower in the hypothyroid patients than in the control and hyperthyroid groups ( $P < 0.004$  and  $P < 0.03$ , respectively)

Results

**Seroprotective rates in hypothyroid and hyperthyroid patients:** Seroprotective rates against tetanus were 100, 80, and 96% in the healthy, hypothyroid, and hyperthyroid groups. The hypothyroid patients exhibited a lower anti-TT seroprotective rate against tetanus than the healthy and hyperthyroid patients ( $P < 0.004$  and  $P$

$< 0.03$ , respectively). Besides, no remarkable difference was found between the healthy and hyperthyroid groups in the seroprotective rate (Fig. 1). In the healthy group, seroprotective rates against tetanus were expressed similarly in the men and women. In the hypothyroid and hyperthyroid groups, all men were seroprotective, while seroprotective rates were found to be 73 and 94.% in the women, respectively (Table 1).

**Table 1.** Serum anti-TT levels and seroprotective rates in healthy, hypothyroid, and hyperthyroid groups

| Groups          | Number | Serum anti-TT levels (IU/ml)• | Skewness    | Kurtosis     | Seroprotective rate [No (%)] |
|-----------------|--------|-------------------------------|-------------|--------------|------------------------------|
| Healthy control | 50     | 3.52 ± 0.31                   | 0.66 ± 0.33 | -0.11 ± 0.66 | 50 (100.0%)                  |
| Hypothyroid     | 50     | 1.62 ± 0.21                   | 1.45 ± 0.33 | 2.20 ± 0.66  | 40 (80.0%)                   |
| Hyperthyroid    | 50     | 4.07 ± 0.32                   | 0.51 ± 0.33 | -0.05 ± 0.66 | 48 (96.0%)                   |

**Fig. 2.** Serum anti-TT levels in the healthy subjects and patients with hypothyroidism and hyperthyroidism; In the hypothyroid patients, serum anti-TT levels were lower than those in the control and hyperthyroid groups ( $P < 0.001$ )

**Anti-TT quantities in the hypothyroid and hyperthyroid patients:** The means of anti-TT titers were  $3.52 \pm 0.31$ ,  $1.62 \pm 0.21$ , and  $4.07 \pm 0.32$  IU/ml, in the healthy, hypothyroid, and hyperthyroid groups, respectively (Table 1). Besides, the anti-TT levels were significantly lower in the hypothyroid patients than in the healthy and hyperthyroid groups ( $P < 0.001$  and  $P < 0.001$ , respectively). However, the difference in the anti-

TT levels between the healthy and hyperthyroid groups was not significant (Fig. 2). In addition, no significant difference was detected between the men and the women in the serum quantities of anti-TT in the healthy individuals and in the thyroid patients. Nevertheless, the hyperthyroid men expressed higher levels of anti-TT than the women (Table 2).

**Table 2.** Serum anti-TT levels and seroprotective rates in healthy, hypothyroid, and hyperthyroid groups based on their gender

| Groups          | Gender | Number | Serum anti-TT levels (IU/ml)• | Seroprotective rates [No (%)] | P-value          |

Discussion

The data presented here indicate that the seroprotective rate and the anti-TT quantities were lower in the hypothyroid patients than in the healthy subjects. Therefore, the hypothyroid patients could have greater vulnerability to tetanus. Lower anti-TT quantities in the hypothyroid subjects could be attributed to some immune irregularities in these individuals. The production of the specific antibodies and the persistence of the immunological memory are complex processes that need coordination between immune cells, especially helper T (Th) cells, B cells, and antigen-presenting cells (APCs), such as dendritic cells and macrophages [14]. The existence of the receptor for thyroid-related hormones was documented on various kinds of leukocytes, such as macrophages, as well as T, and B lymphocytes [9]. Therefore, it is logical that immune functions are impaired in hypothyroid individuals. It has been reported that the B cell maturation is impaired in mice with the deficient thyroid hormone, yet the administration of T3 and T4 fully recovered this deficiency [15]. In addition, hypothyroid mice displayed a lower number of B cells in their bone marrow than normal ones [15].

Vaccination is the most efficient strategy for providing immunity against infectious diseases mediated via immunologic memory induction [16]. The low anti-TT quantities in the hypothyroid patients could be partly due to immunological memory defects that probably made these patients susceptible to infectious diseases.

The present study showed that the anti-TT levels were higher in the hyperthyroid individuals than in the hypothyroid patients. Besides, a higher number of peripheral blood lymphocytes and an enhanced lymphocyte proliferation response were observed in the hyperthyroid animals. Moreover, higher serum IgG and IgA concentrations were observed in the hyperthyroid women than in the healthy women [10]. Although the seroprotective rate was lower in the hyperthyroid patients than in the

healthy subjects, the anti-TT quantities did not seem to be reduced in these patients.

Our results showed that in both hypothyroid and hyperthyroid groups, seroprotective rates were greater in the men than in the women. Similar results were reported in other investigations [17-19]. The elevated levels of anti-TT in the men could have been due to higher exposure to *Clostridium tetani*, leading to higher protective rates. In fact, this could be attributed to greater accident rates in the men. Men with a history of dirty ulcers or prevalent soil contamination generated higher anti-TT quantities [16]. Moreover, a group of men might have been vaccinated against tetanus during their military service. More investigations need to be carried out to explain reasons for the greater seroprotective rate against tetanus in men than in women.

Conclusion

In the present study, lower anti-TT levels were detected in the hypothyroid patients, indicating that hypothyroidism could negatively affect anti-TT levels and immunity against tetanus. The patients' gender could influence the seroprotective rates against tetanus. However, the immunity against tetanus could not be affected in the hyperthyroid subjects. More studies need to be conducted in this field to provide more data to be considered in health programs.
